Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

UV-Light Induced Vibrational Coherences, the Key to Understand Kasha Rule Violation in *trans*-Azobenzene

ABSTRACT

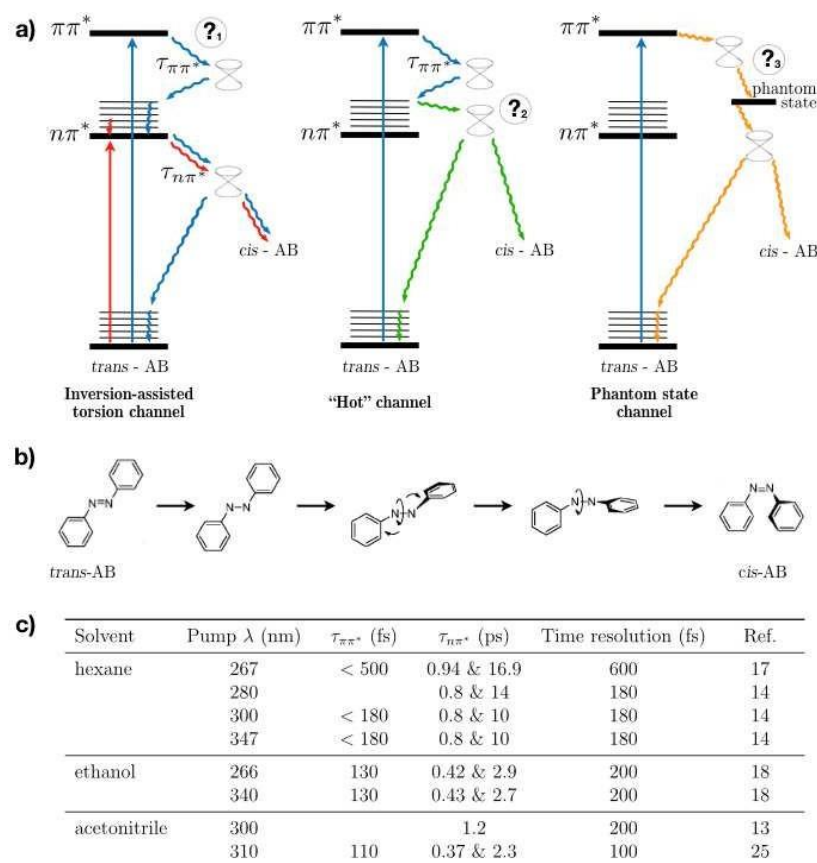

We combine sub-20-fs transient absorption spectroscopy with state-of-the-art computations to study the ultrafast photoinduced dynamics of *trans*-azobenzene (AB). We are able to resolve the lifetime of the $\pi\pi^*$ state, whose decay within ca. 50 fs is correlated to the build-up of the $n\pi^*$ population and to the emergence of coherences in the dynamics, to date unobserved. Nonlinear spectroscopy simulations call for the CNN in-plane bendings as the active modes in the sub-ps photoinduced coherent dynamics out of the $\pi\pi^*$ state. Radiative to kinetic energy transfer into these modes drives the system to a high-energy planar $n\pi^*/$ ground state conical intersection, inaccessible upon direct excitation of the $n\pi^*$ state, that triggers an ultrafast (0.45 ps) non-productive decay of the $n\pi^*$ state and is thus responsible for the observed Kasha rule violation in UV excited *trans*-AB. On the other hand, *cis*-AB is built only after intramolecular vibrational energy redistribution and population of the NN torsional mode.

TOC GRAPHICS

1
2
3 Photochromism is at the heart of light-powered nanomachines, also known as molecular photoswitches,
4
5 which can be reversibly switched between two or more stable configurations by exposure to light¹. Over
6
7 the years the technological potential of molecular switches has been demonstrated in various
8
9 applications like optical storage devices², triggers for peptide folding³⁻⁴, light-gated ion channel control⁵
10
11 or nonlinear optical materials⁶ to name a few. Azobenzene (AB) based compounds are prominent
12
13 photoswitches which undergo an ultrafast (picosecond) *trans-cis* photoisomerization associated with
14
15 changing the conformation of the central N=N double bond. AB has favorable photochromic properties,
16
17 such as a significant change in geometry of the molecule upon isomerization, photoactivity even under
18
19 strong constraints⁷⁻¹¹ and discrete absorption bands, allowing to selectively address either the *trans* or *cis*
20
21 configurations. It is therefore not surprising that considerable effort has been put into scrutinizing its
22
23 photoactivity^{8,12-39}. A summary of the most notable research is provided in section 8 of the
24
25 Supplementary Information (SI). Nowadays it is generally accepted that the decay to the ground state
26
27 (GS) upon $\pi\pi^*$ excitation of *trans*-AB involves an extended conical intersection (CI) seam reached
28
29 through both torsion and bending (“inversion-assisted torsion”, Scheme 1(b)). However, there is still a
30
31 controversy over key aspects of the photoisomerization process of $\pi\pi^*$ -excited *trans*-AB. To date the
32
33 temporal resolution of transient experiments has not permitted to determine the lifetime of the $\pi\pi^*$ state
34
35 (?₁ in Scheme 1(a)). To the best of our knowledge a value of 110 fs²⁵ is the shortest lifetime reported in
36
37 the literature, which is comparable to the used instrumental response function (see Scheme 1(c)) for a
38
39 literature survey of $\pi\pi^*$ and $n\pi^*$ lifetimes after $\pi\pi^*$ excitation). Following the ultrafast decay of the
40
41 spectral features associated with the $\pi\pi^*$ state a bi-exponential (sub-ps and several ps) decay of the $n\pi^*$ -
42
43 associated signatures has been reported. While there is strong evidence for a pathway common to $\pi\pi^*$ -
44
45 and $n\pi^*$ -excitation^{18,20,25-26} (i.e. inversion-assisted torsion, shown in blue and red in Scheme 1(a)) it is
46
47 still unclear what is the nature of the molecular motion associated with the sub-ps relaxation dynamics.
48
49 It is speculated that this ultrafast channel involves a CI inaccessible upon $n\pi^*$ excitation^{25,29} (labeled
50
51
52
53
54
55
56
57
58
59
60

“hot” channel in Scheme 1a)), but it is yet to be demonstrated whether this relaxation channel is reactive (i.e. leading to *cis*-AB) or non-reactive and whether it is responsible for the violation of Kasha rule⁸, characterized by a 50% decrease of the quantum yield (QY) upon excitation of *trans*-AB with UV light (?₂ in Scheme 1a)). Related to this, the involvement of “dark” states (labeled “phantom” state in Scheme 1a)), brought into discussion by several authors^{21,28,33} as a possible reason for the QY decrease, still remains controversial (?₃ in Scheme 1a)).

Scheme 1. a) Energy diagrams of the relaxation channels in *trans*-AB after $n\pi^*$ - and $\pi\pi^*$ - excitation, proposed in the literature. b) The *trans*→*cis* mechanism of inversion-assisted torsion. c) A literature survey of the $\pi\pi^*$ and $n\pi^*$ lifetimes after $\pi\pi^*$ excitation.

In this paper, we address these questions by combining high time resolution transient absorption (TA) spectroscopy and multiconfigurational wavefunction techniques. We perform TA with sub-20-fs pump

1
2
3 pulses at 320 nm and broadband probe pulses ranging from the visible (350-700 nm) to the UV (250-
4
5 380 nm), which: (a) allow to resolve the dynamics in the $\pi\pi^*$ state prior to its ultrafast (sub-100 fs)
6
7 decay; (b) resolve coherent ES dynamics in the $n\pi^*$ state; (c) explore the deep UV window (250-280
8
9 nm) rich with spectroscopic fingerprints of reactant and photoproduct. *Ab initio* molecular dynamics
10
11 (MD) simulations within the second order multi-configurational perturbation theory (CASPT2)
12
13 framework utilizing a full- π active space disclose the relaxation routes from the Franck-Condon (FC)
14
15 point on the $\pi\pi^*$ state to the GS, thereby confirming the ultrafast $\pi\pi^* \rightarrow n\pi^*$ decay. The simulations
16
17 show that the “hot” $n\pi^*$ population can decay to the GS through an energetically high lying near-planar
18
19 region of the $n\pi^*/GS$ CI seam not accessible upon selective excitation of the $n\pi^*$ state, thus confirming
20
21 the existence of the “hot” decay channel (Figure 1a)). We argue that this channel is non-reactive and,
22
23 thus, the prime reason for the violation of the Kasha rule. Combining high-level electronic structure
24
25 calculations with theoretical nonlinear spectroscopy techniques we simulate the TA spectra, explicitly
26
27 incorporating the, so far, theoretically elusive excited state absorption (ESA) features and their
28
29 vibrational lineshape broadening, therefore uncovering the nature of the coherent oscillations observed
30
31 in the experiment.

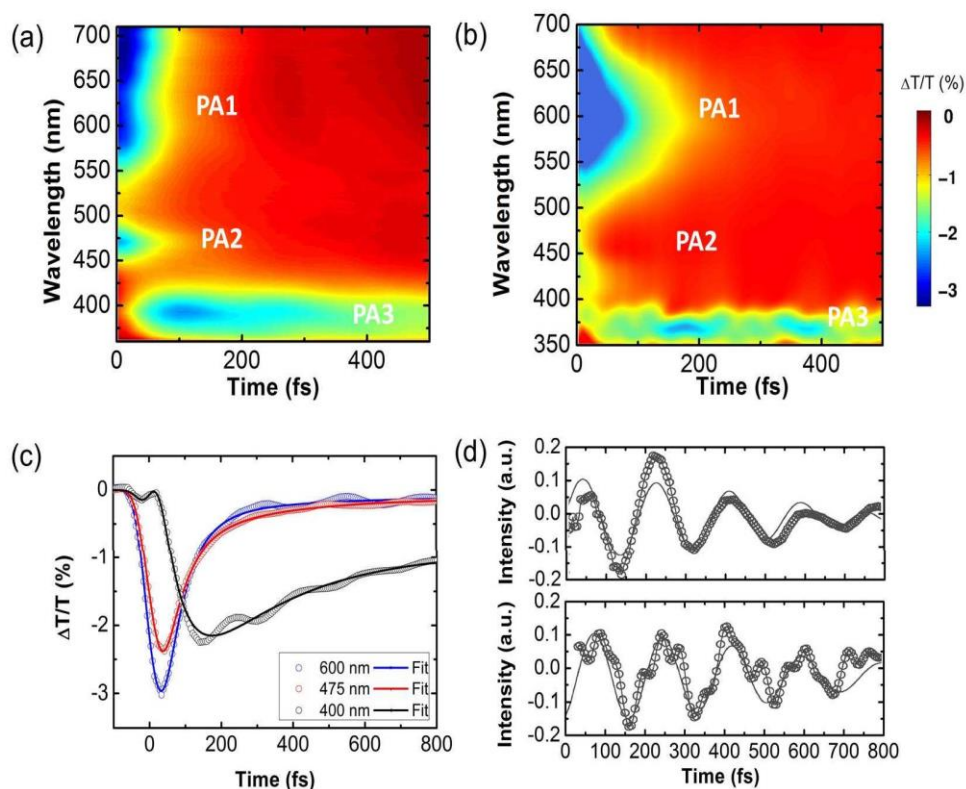

Figure 1. (a) Experimental (ethanol) and (b) theoretical (gas-phase) TA maps of *trans*-AB in the visible spectral window during the first 500 fs with (c) extracted dynamics at 400, 475 and 600 nm. (d) Intensity oscillations (residuals): experimental at 400 nm (top) and computed at 370 nm (bottom). Open dots represent the experimental (theoretical) data and the solid line the fits.

Trans-AB in ethanol solution was pumped with 16-fs UV pulses centered at 330 nm, resonant with the $\pi\pi^*$ transition, and probed over a broad wavelength range. The experimental setup has been described elsewhere⁴⁰⁻⁴², whereas the sample preparation details and the linear absorption (LA) spectrum are provided in the SI. Figure 1(a) shows the TA spectra in the visible (VIS) between 360-700 nm for the first 500 fs. In agreement with previous studies^{14,17,18,25}, at early times (<100 fs) we observe two

53 photoinduced absorption (PA) bands: a broad intense band ranging from 550 nm to 700 nm (PA1) and a
54 narrower band between 450 nm and 500 nm (PA2). A global fit of the data⁴⁹⁻⁵⁰(see SI for details) reveals
55

1
2
3 that PA1 and PA2 decay with a lifetime of ~ 50 fs (Figure 1(c)), with the concurrent rising of a new PA
4
5 band (PA3), formed with the same time constant, peaking around 400 nm. Considering their ultrafast
6
7 decay and their absence in the spectra when the $n\pi^*$ state is selectively excited, PA1 and PA2 have been
8
9 previously assigned to the $\pi\pi^*$ state^{18,25-26}. PA3, on the other hand, is a fingerprint of the $n\pi^*$ state¹⁸⁻
10
11 ^{20,25,26}. It shows oscillatory behavior with a period of 170 fs (195 cm^{-1}), an indication of coherent
12
13 dynamics, damped after ≈ 2 ps. Similar oscillatory patterns are observed also at 600 nm and 670 nm,
14
15 after the initial fast amplitude decay. Measurements on longer timescale (Figures S20 and S21, SI) show
16
17 a PA3 decay described by the sum of three exponentials with time constants 0.45ps, 2.5 ps and ~ 9 ps, in
18
19 agreement with previous studies^{18-20,25}.
20
21
22
23

24 Figure 1(b) depicts the simulated TA map in the same temporal and spectral windows. The
25
26 simulations protocol utilizes non-linear response theory, the system's response to the perturbation by
27
28 three external electric fields is expressed within the framework of cumulant expansion of Gaussian
29
30 fluctuations (CGF)⁴³⁻⁴⁵ and the parameters were obtained with electronic structure computations within
31
32 the framework of multi-configurational wavefunction theory⁴⁶⁻⁴⁸. The simulation protocol is outlined in
33
34 Sections 1 and 2 of the SI. Despite the notable blue-shift of the computed signals with respect to
35
36 experiment (that falls within the accuracy of the computational approach) the agreement is excellent.
37
38 These results allow us to identify the nature of the underlying transitions. The rapidly decaying PA1 and
39
40 PA2 features are fingerprints of the $\pi\pi^*$ state, which arise due to the spectral overlap of ESA bands
41
42 associated with several electronic transitions. Each of the two ESA signals consists of three higher lying
43
44 states which are bright from the $\pi\pi^*$ state and have a pronounced multiconfigurational nature and
45
46 significant weights of doubly excited configuration state functions (SI, PA1: section 3.2.2, Figure S12
47
48 and Table S5).
49
50
51
52

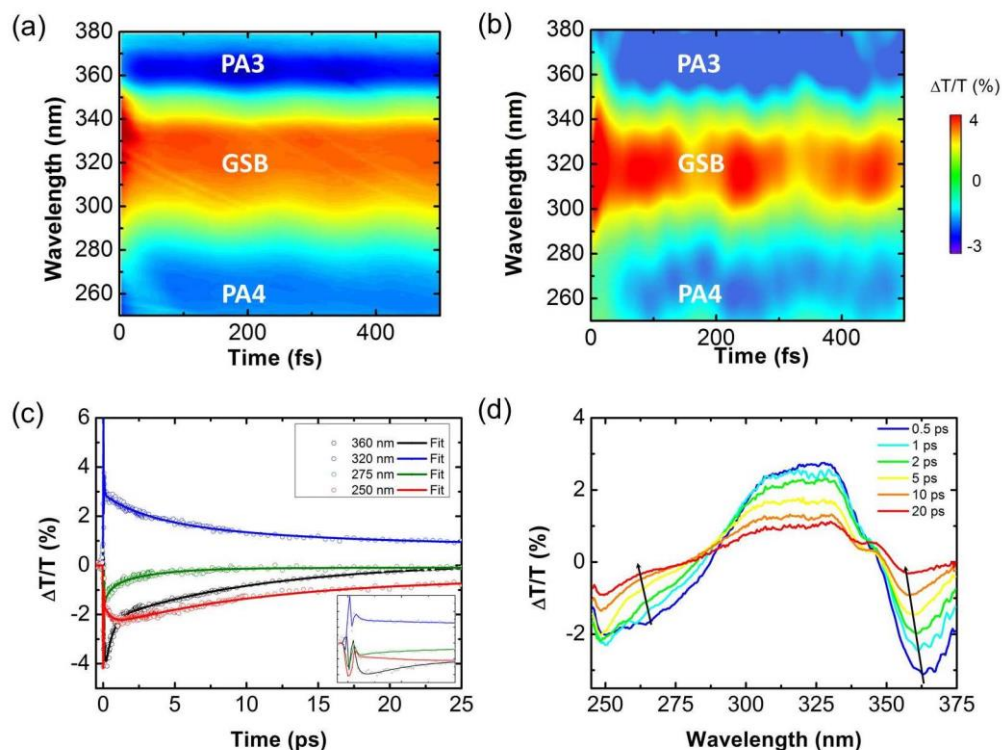

Figure 2. (a) Experimental (ethanol) and (b) theoretical (gas-phase) TA data of *trans*-AB probed in the ultraviolet range (245–380 nm). (c) Extracted dynamics at three selected wavelengths (open circles) and fit of the data (solid lines). Inset: Zoom up to 2 ps delay time. (d) Extracted transient spectra at several delay times. Arrows highlight the blue-shift of the maxima of the transient absorption signals around 270 nm and 360 nm.

ESA bands provide an indirect probe of the coherent vibrational dynamics in the ES reflected in peak shifts and intensity beats, whose magnitude is correlated to the electronic structure of the underlying states. The states contributing to PA1 and PA2 show pronounced sensitivity to following ES-active modes: $606/614\text{ cm}^{-1}$, 666 cm^{-1} , 924 cm^{-1} , 1161 cm^{-1} , 1397 cm^{-1} and 1628 cm^{-1} , associated with bending and stretching deformations in the central CNNC fragment (Figures S5 and S6 in the SI). The

53 ultrafast decay of the population covers coherent oscillatory features at early times. The picture is
54 clearer when looking at the 400 nm trace (Figure 1(c)), the fingerprint of the $n\pi^*$ state. It arises from a
55

56
57
58
59
60

1
2
3 single ESA contribution to a higher lying state (SI, section 3.2.3 and Table S6). As noted above, the
4
5 intensity of PA3 shows clear oscillatory behavior with a 170-fs period. Our simulations (Figure 1(d))
6
7 reproduce the intensity beat pattern rather well. Remarkably, only one dominant vibrational feature (195
8
9 cm^{-1}) is extracted from both the experiment and simulation despite the fact that time-resolved Raman¹⁷
10
11 and photoionization³¹ spectroscopies have resolved a plethora of modes involved in the coherent
12
13 dynamics on the $n\pi^*$ state after selective $n\pi^*$ excitation. Oddly enough, although the CASSCF
14
15 frequencies at the $n\pi^*$ minimum provide a 205 cm^{-1} mode (symmetric CNN bending) that could be
16
17 tentatively assigned to the experimental observation, our simulations demonstrate that the ES
18
19 responsible for PA3 is rather insensitive to the dynamics in this mode (Figure S8, SI). Instead, our
20
21 simulations show that the 660 cm^{-1} and 852 cm^{-1} modes, both having strong CNN bending contribution,
22
23 strongly modulate the absorption cross-section of the ES and are the source of the observed intensity
24
25 beats (see Chapter 3.2 in the SI). These frequencies have been reported to be particularly intense in time-
26
27 resolved Raman studies^{15, 25} and in photoionization spectroscopy³¹. Together with the 205 cm^{-1} CNN
28
29 bending and the 300 cm^{-1} CCN bending modes, they constitute a quartet of “hot” modes that accumulate
30
31 almost 10000 cm^{-1} reorganization energy upon $\pi\pi^* \rightarrow n\pi^*$ decay. We also note a second $n\pi^*$ fingerprint
32
33 PA signal around 600 nm which has been reported previously for selective $n\pi^*$ excitation^{18,25}. Weak
34
35 coherent oscillations are resolved in the ps-range. For this ESA three modes, 205 cm^{-1} , 660 cm^{-1} and 852
36
37 cm^{-1} are predicted to contribute (Figure S13 in the SI).

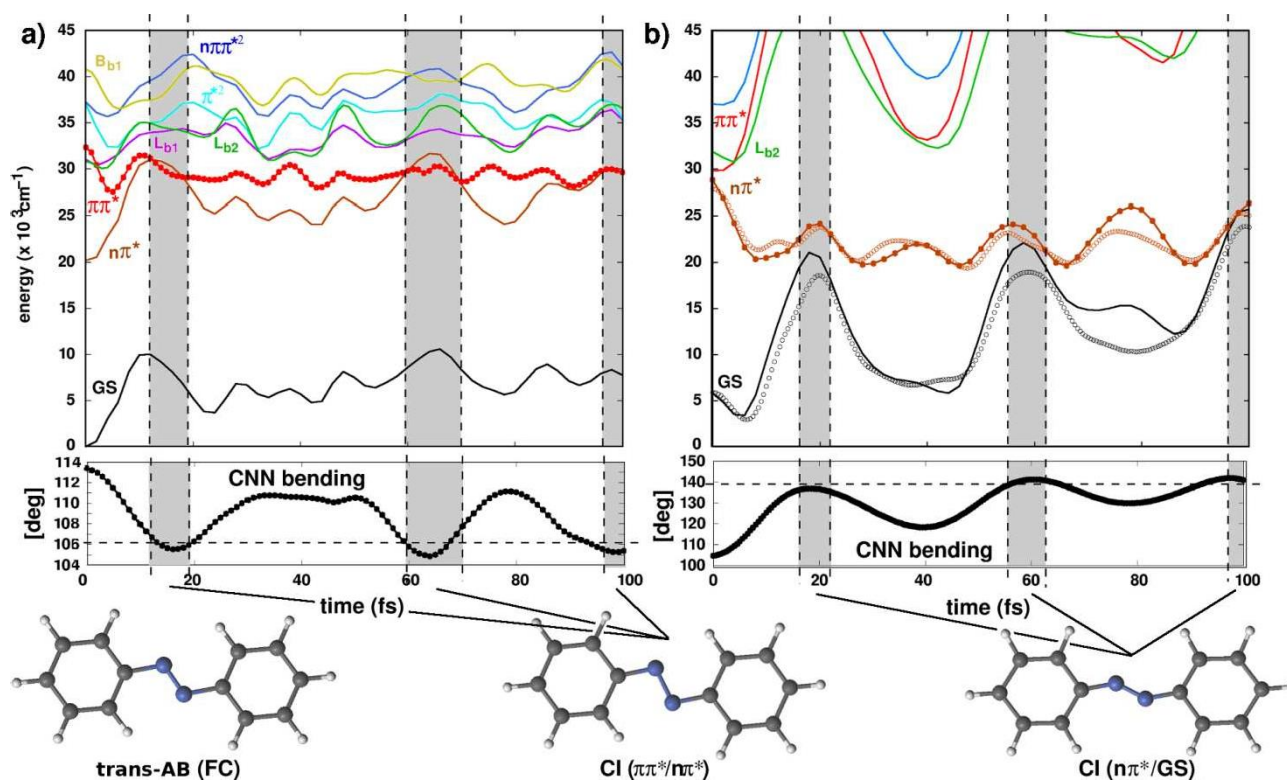

Figure 3. Structure of the low-lying ES manifold along the 0K MD in the $\pi\pi^*$ state (red) initiated at the FC point (a) and along the $n\pi^*$ state (brown) initiated at a CI between $\pi\pi^*$ and $n\pi^*$ (b). Both, symmetry-constrained (solid lines) and fully unconstrained (dashed lines) simulations were performed starting from a planar and a non-planar CI geometry, respectively. The evolution of CNN bending along the symmetry-constrained trajectories is shown. Gray areas indicate recurrent crossings between $\pi\pi^*$ and $n\pi^*$ (a), as well as between $n\pi^*$ and GS.

A second set of measurements was performed with UV (250-380 nm) probe. Figure 2(a) shows the TA map during the first 500 fs compared to the theory (panel (b)). A longer timescale measurement is given in the SI (Figures S20 and S21). In addition to PA3, two new spectral features are observed: the GSB in the range 300-340 nm, which decays with a time constant of 11 ps (Figure 2(c)) and a PA band ranging from 245 to 280 nm (PA4). Global analysis reveals 0.46, 2.8 and 11 ps time constants. These values

54
55

match those of PA3, indicating that the nature of PA4 and PA3 must be similar. This notion is supported

53
54
55
56
57
58
59
60

1
2
3 by the computations, which resolve also this ESA feature of the $n\pi^*$ state (Figure 2(b) and SI, section
4 2.2.3 and Table S6). There is, however, one noticeable difference between PA3 and PA4: by comparing
5
6 the TA spectra (Figure 2(d)), one observes that while the signals at 365 nm and 270 nm decrease in
7
8 amplitude during the first 2 ps accompanied by a blue-shift, PA4 shows a simultaneous increase in
9
10 amplitude at the bluest frequencies (245-260 nm) on the same timescale. At longer delay times the entire
11
12 band relaxes with a lifetime of 11 ps, leaving a finite long-lived offset due to the formed *cis*-AB.
13
14 Correspondingly, a fit of the signal at 250 nm shows a build-up time of 0.46 ps, and decay constant of
15
16 11 ps. A global analysis of the data (SI, Figure S23) reveals that the bluest region (245-260 nm) is
17
18 dominated by the 0.46 ps and 11 ps components, whereas in the reddest region (260-280 nm) the 0.46
19
20 and 2.8 ps components present the largest amplitude. Thus, these two spectral regions of PA4 capture
21
22 different processes whose signatures overlap spectrally and temporally. The LA spectrum of *cis*-AB (see
23
24 Figure 1 in ref. 25) shows a peak at 250 nm. Thus, one might tentatively assign the build-up of intensity
25
26 at this wavelength to the formation of *cis*-AB in the GS on a sub-ps time scale. However, we argue that
27
28 we observe more probably a signature of the “hot” *trans*-AB reactant. Kovalenko *et al.* estimated that
29
30 $\approx 50\%$ of the $n\pi^*$ population returns to the GS within the first ps. Even if we assumed that all of the *cis*-
31
32 AB photoproduct ($\sim 12\%$ QY) is formed through this ultrafast channel, at least four times more “hot”
33
34 reactant would be recovered simultaneously. It is well known that a “hot” GS gives rise to a PA band
35
36 red-shifted from the GSB, which decays by vibrational cooling on a ps time scale. The LA spectrum of
37
38 *trans*-AB has a narrow band peaking at ≈ 230 nm, assigned by our computations to a transfer of
39
40 electronic density between the central CNNC fragment and the benzene rings (SI, Table 4). Thus, we
41
42 interpret the 250-nm signal as the build-up of the “hot” GS of the reactant, whose PA overlaps with the
43
44 270 nm ESA of the $n\pi^*$ state.
45
46
47
48
49
50
51
52

1
2
3 To validate this interpretation and explain the molecular motions governing the ultrafast (sub-ps)
4 decay of a major part of the ES population, we performed adiabatic *ab initio* MD simulations utilizing
5 quantum mechanical gradients at CASPT2 level of theory⁵¹ (Figure 3). A single trajectory was initiated
6 in the FC point (C_{2h} symmetry) of the bright $\pi\pi^*$ state (red dotted line in Figure 3(a)) without initial
7 kinetic energy and the energies of the close lying electronic states were monitored for the first 100 fs
8 (further details on the simulation protocol are provided in Chapter 4 of the SI). We found a high density
9 of electronic states in the near- and deep-UV energy window (250-400 nm). Two spectroscopically
10 “dark” states involving the benzene rings (purple, Lb1, and green, Lb2, SI, Table S4) appear near
11 isoenergetic with the $\pi\pi^*$ state in the FC point. Further states involve the doubly excited π^{*2} (cyan), the
12 mixed $n\pi\pi^{*2}$ transition (blue) and the aforementioned “bright” state responsible for the 230 nm band in
13 the LA spectrum (Bb1, shown in dark ocher, SI, Table 4). The picture is completed by the $n\pi^*$ state at
14 ~500 nm, the lowest ES in *trans*-AB. In agreement with Raman data^{15,23,31} the vibrational dynamics in
15 the $\pi\pi^*$ state is governed by the N=N and C-N stretching modes with 1397 cm^{-1} and 1618 cm^{-1}
16 frequencies. It is apparent that the $\pi\pi^*$ state crosses several times with the $n\pi^*$ state, which exhibits a
17 pronounced destabilization in intervals of ca. 40 fs. These recurrent crossings (gray areas in Figure 3(a))
18 are correlated to the in-plane CNN bending. We clarify, however, that the $\pi\pi^* \rightarrow n\pi^*$ population transfer
19 is symmetry-forbidden for planar geometries. Out-of-plane deformations are required to invoke a non-
20 zero non-adiabatic coupling. Upon releasing the symmetry constraints we optimized a non-planar
21 asymmetric CI (SI, Chapter 2.2.3) with a CNNC dihedral of 13°. It is, thus, evident that an extended
22 non-planar $\pi\pi^*/n\pi^*$ CI seam is available to *trans*-AB. The need to undergo out-of-plane deformations
23 for efficient population transfer might explain the mismatch between the experimental $\pi\pi^*$ lifetime of
24 52 fs and the theoretical simulation revealing a crossing as early as 15 fs.

49
50
51
52
53
54 The “dark” benzenic¹⁷ and the doubly excited π^{*2} states have been suggested to participate in the
55 deactivation of the $\pi\pi^*$ state^{28,33} (“phantom” states). The best candidate for a potential population
56
57
58
59
60

1
2
3 bifurcation is one of the benzenic states Lb2 (green line in Figure 3(a)) due to its energetic proximity to
4 the $\pi\pi^*$ state and to the finite (symmetry-allowed) probability for non-adiabatic population transfer even
5
6 for planar geometries. However, our simulations show that this state remains above the $\pi\pi^*$ state
7
8 throughout the dynamics, suggesting that the direct $\pi\pi^* \rightarrow n\pi^*$ decay is the most efficient channel, in
9
10 agreement with our high time resolution TA results. We emphasize that the 0K simulations do not
11
12 disprove the participation of “phantom” states but merely show that latter are not necessary to
13
14 rationalize the spectroscopic features of the present study.
15
16
17

18
19 Starting from the non-planar CI geometry we followed the molecular dynamics in the $n\pi^*$ state
20
21 through a fully unconstrained simulation for 200 fs (dashed lines in Figure 3(b)). We chose the non-
22
23 planar geometry as a starting point of the simulation to address potential activation of either the
24
25 (asymmetric) inversion or the torsion mechanism at early times. MD simulations were also performed
26
27 under C_{2h} symmetry (solid lines in Figure 3(b)) starting from a planar $\pi\pi^*/n\pi^*$ CI. The $n\pi^*$ exhibits a
28
29 pronounced destabilization in the $\pi\pi^*/n\pi^*$ CI region, due to the far out-of-equilibrium displacement
30
31 along the CNN coordinate with a value of 127° in the $n\pi^*$ equilibrium. After crossing to the $n\pi^*$ state
32
33 the wavepacket converts upon relaxation nearly 10000 cm^{-1} potential energy, stored in the CNN bending
34
35 modes, to kinetic energy. Despite the unconstrained approach, we observe only in-plane dynamics
36
37 during the first 200 fs governed by the same four “hot” CNN modes responsible for the intensity beat
38
39 pattern observed in the VIS spectra. In fact, the unconstrained dynamics follows closely the dynamics
40
41 within C_{2h} symmetry. The vibrational energy inserted in the bending modes drives AB within 20 fs
42
43 away from the $\pi\pi^*/n\pi^*$ CI far beyond the $n\pi^*$ equilibrium towards a CI with the GS situated $\sim 5000\text{ cm}^{-1}$
44
45 above the $n\pi^*$ minimum and showing an increase of the CNN angles to 143° ²⁹. The CI region is
46
47 revisited every 40 fs. It is this energetically high lying segment of the CI seam with nearly planar
48
49 geometries, which remains inaccessible after direct $n\pi^*$ excitation, that effectively funnels half of the
50
51 $n\pi^*$ population back to the GS within the first 500 fs after $\pi\pi^*$ excitation. We argue that this channel

3 Scheme 1a)). The coherent dynamics associated with this non-reactive channel driven by the in-plane
4 CNN bending mode is the source of ESA intensity beats in the transient spectra and reduced QY. *trans*
5 → *cis* isomerization requires IVR into the torsional mode, takes an order of magnitude longer (2-4 ps),
6 is incoherent and proceeds in analogous way upon UV and VIS excitation (500 nm, $\pi\pi^*$ excitation).
7
8 Dashed lines show projection in the bending-torsion plane. Coloring according to Scheme 1a). Energy
9 values in eV.

18 In conclusion, we have combined TA spectroscopy with sub-20 fs temporal resolution in the UV range
19 with state-of-the-art computational tools to study the ultrafast photodynamics of *trans*-AB. We were
20 able to resolve the lifetime of the $\pi\pi^*$ state, the build-up of the $n\pi^*$ population and the following
21
22 coherent oscillatory dynamics. We observe a single ultrafast lifetime (~ 50 fs) of the $\pi\pi^*$ state which is
23 correlated to the build-up of the $n\pi^*$ ESA. Theoretical simulations reproduce with remarkable accuracy
24 the positions of all ESA bands from the $\pi\pi^*$ and $n\pi^*$ states and reveal the origin of the ps-lasting
25 oscillations of the intensity of the photoinduced absorption signals and, thus, the nature of the
26 vibrational dynamics activated immediately after decay to the $n\pi^*$ state. Four “hot” modes, all
27 characterized by strong symmetric in-plane bending deformations in the central CNNC fragment, were
28 identified: 200 cm^{-1} , 300 cm^{-1} , 650 cm^{-1} , 850 cm^{-1} . The observed intensity beat pattern is a signature of
29 the localization of large amount of energy (10000 cm^{-1}) in these four modes during the first 1 ps causing
30 strong modulations of the absorption cross section. Radiative to kinetic energy transfer opens a non-
31 radiative channel to the GS, inaccessible upon $n\pi^*$ excitation (Figure 4). The interplay between theory
32 and experiment allows us to assign the so-called “CNN-bending” channel as the main reason behind the
33 violation of the Kasha rule and behind the QY reduction at shorter wavelengths, *cis*-AB being formed
34 only after IVR from the bending modes into the torsion on the ps time scale. Finally, neither the
35 experimental nor the theoretical results call for additional ESs in order to describe the $\pi\pi^*$ depopulation
